High-Index Faceted Nanocrystals as Highly Efficient Bifunctional Electrocatalysts for High-Performance Lithium–Sulfur Batteries

Bo Jiang¹, Da Tian¹, Yue Qiu¹, Xueqin Song¹, Yu Zhang³, Xun Sun¹, Huihuang Huang¹, Chenghao Zhao¹, Zhikun Guo¹, Lishuang Fan^{1,2} ✉, Naiqing Zhang^{1,2} ✉

HIGHLIGHTS

- High-index faceted Fe_2O_3 nanocrystals with abundant unsaturated Fe sites not only have strong adsorption capacity to anchor LiPSs but also have superior catalytic activity to facilitate the redox conversion of LiPSs and reduce the decomposition energy barrier of Li_2S .
- Our work deepens the comprehending of facet-dependent activity of catalysts in Li–S chemistry and affords a novel perspective for the design of advanced sulfur electrodes.

ABSTRACT Precisely regulating of the surface structure of crystalline materials to improve their catalytic activity for lithium polysulfides is urgently needed for high-performance lithium–sulfur (Li–S) batteries. Herein, high-index faceted iron oxide (Fe_2O_3) nanocrystals anchored on reduced graphene oxide are developed as highly efficient bifunctional electrocatalysts, effectively improving the electrochemical performance of Li–S batteries. The theoretical and experimental results all indicate that high-index Fe_2O_3 crystal facets with abundant unsaturated coordinated Fe sites not only have strong adsorption capacity to anchor polysulfides but also have high catalytic activity to facilitate the redox transformation of polysulfides and reduce the decomposition energy barrier of Li_2S . The Li–S batteries with these bifunctional electrocatalysts exhibit high initial capacity of 1521 mAh g^{-1} at 0.1 C and excellent cycling performance with a low capacity fading of 0.025% per cycle during 1600 cycles at 2 C. Even with a high sulfur loading of 9.41 mg cm^{-2} , a remarkable areal capacity of 7.61 mAh cm^{-2} was maintained after 85 cycles. This work provides a new strategy to improve the catalytic activity of nanocrystals through the crystal facet engineering, deepening the comprehending of facet-dependent activity of catalysts in Li–S chemistry, affording a novel perspective for the design of advanced sulfur electrodes.

1 Introduction

The booming progress of luggable electronic devices and electric vehicles urgently needs electrochemical energy storage equipment with higher power density and lower cost than lithium-ion batteries (LIBs) [1–4]. Lithium–sulfur (Li–S) batteries with high theoretical capacity (1672 mAh g⁻¹), remarkable energy density (2600 Wh kg⁻¹) and low cost, as one of the most promising substitutes to the current LIBs, have attracted widespread attention and ever-increasing research enthusiasm [1, 5–8]. However, the commercial application of Li–S batteries is still constrained by many challenges. The inevitable dissolution of lithium polysulfides (LiPSs) intermediates in the electrolytes and the shuttling of LiPSs between the cathode and anode result in low sulfur utilization, swift capacity degradation and the corrosion of lithium anode [9–16]. In addition, the sluggish redox kinetics resulting from insulating sulfur and Li₂S during discharge/charge cycles limits the efficient conversion of sulfur species, impairing the rate performance and cycling stability of Li–S batteries [17–22]. Consequently, various materials have been developed and applied to Li–S batteries to tackle aforementioned issues, such as carbon matrix materials [23, 24], metal oxides [3, 25–27], metal nitrides [28, 29] and metal sulfides [30–32].

Although constructing these host materials improves the electrochemical performance of Li–S batteries to a certain extent, most of the existing researches mainly dedicated on the screening of catalytic materials which can anchor and reversibly transform LiPSs, as well as optimizing electrode materials by designing the composition, microstructure and electronic structure of the bulk phase. It is well known that both the adsorption of LiPSs and the catalytic conversion of sulfur species occur on the surfaces of electrode material [33, 34]. The surface structure of the electrode materials will directly affect the adsorption and catalytic conversion of sulfur species. However, this significant crystal facet effect in the sulfur electrochemistry has been neglected and the corresponding researches have not been reported so far. The different crystal facets exposed on electrode materials have disparate atomic arrangement [35–38], especially the high-index crystallographic planes with high densities of periodic atom steps, ledges and unsaturated coordinated sites [39–43], which

may effectively regulate the adsorption and catalytic transformation of sulfur species.

Herein, the crystal facet effect in Li–S electrochemistry was systematically investigated by the design and synthesis of the high-index facet nanocrystals based on a series of electrochemical experiments and density functional theory (DFT) calculations. This work exhibited profound insight into the structure–activity relationship between the surface structures of crystal materials and the redox kinetics for sulfur species, which provided more direct theoretical basis for the rational design of advanced Li–S electrode materials in the future. In view of the low cost and nontoxicity [44–46], Fe₂O₃ nanocrystals with different facets were fabricated on the reduced graphene oxide (Fe₂O₃-G) for investigating the crystal facet effect. The theoretical and experimental results demonstrated that concave Fe₂O₃ nanocubes (C-Fe₂O₃) bounded by high-index {12 $\bar{3}$ 8} and {13 $\bar{4}$ 4} facets not only manifested superior inhibition effect on the shuttle of polysulfides but also had more robust catalytic activity for the transformation of sulfur species than Fe₂O₃ pseudocubes (P-Fe₂O₃) enclosed by {01 $\bar{1}$ 2} facets. The abundant unsaturated coordinated Fe sites on the high-index faceted C-Fe₂O₃ as the active centers boosted the chemical adsorption for LiPSs, accelerated polysulfides conversion, in particular, enhanced the decomposition kinetics of Li₂S, significantly improving the rate performance and cycle stability of Li–S batteries. With C-Fe₂O₃-G as the bifunctional electrocatalyst, the assembled batteries delivered a high initial specific capacity of 1521 mAh g⁻¹ at 0.1 C and long-term cycle stability with a low capacity attenuation rate of 0.025% each cycle for 1600 cycles at 2 C. Moreover, a prominent areal capacity of 7.61 mAh cm⁻² was maintained under a high sulfur loading of 9.41 mg cm⁻² after 85 cycles at 0.2 C.

2 Experimental Section

2.1 Synthesis of C-Fe₂O₃-G, P-Fe₂O₃-G and Reduced Graphene Oxide

Graphite oxide was synthesized from natural graphite flakes employing a modified Hummers method. Firstly, a graphene oxide (GO) colloidal solution of 5 mg mL⁻¹ was fabricated via a sonication treatment for one hour with 40 mg of GO in

8 mL of deionized water. In a typical synthesis of C-Fe₂O₃-G, 1.616 g of Fe(NO₃)₃·9H₂O and 0.2 g of copper acetate were dissolved in deionized water (12 mL) under magnetic stirring. After twenty minutes, the homogeneous solution was mixed with above-mentioned 8 mL of GO colloidal solution and continued to be stirred for one hour in ambient atmosphere. Then 20 mL of ammonia solution (25 wt%) was quickly added into these mixtures under vigorous stirring and keep stirring for ten minutes. Finally, the resulting mixtures were transferred into a 100-mL Teflon-lined stainless steel autoclave and hydrothermally reacted at 160 °C for sixteen hours. After cooling down to room temperature naturally, the products were collected by centrifugation and washed with deionized water for several times, and subsequently freeze-dried at -50 °C to obtain C-Fe₂O₃-G powder. In the same experimental process, P-Fe₂O₃-G was synthesized by replacing copper acetate with nickel acetate and reduced graphene oxide were synthesized without the addition of metal salts.

2.2 Material Characterization

The morphologies, structures and elemental estimation of the as-prepared products were performed via the transmission electron microscopy (TEM, FEI Tecnai G2 F30) and scanning electron microscopy (SEM, Hitachi SU8010). The crystal structures of the as-prepared materials were characterized by X-ray diffractometer (PANalytical X'Pert PRO) with Cu K α radiation (40 mA, 40 kV). The contents of different components were measured by a thermogravimetric analyzer system (Linseis STA PT 1600). The specific surface areas and pore size distribution of the synthesized materials was explored by the Brunauer–Emmett–Teller (BET) method (using ASAP 2020, Micromeritics). X-ray photoelectron spectroscopy (XPS) measurements were taken on Thermo Scientific X-ray photoelectron spectrometer. The UV–Vis analysis was conducted with a Shimadzu UV-2450 spectrophotometer.

More details of other syntheses and characterizations can be seen in Supporting Information.

3 Results and Discussion

3.1 Characterization of C-Fe₂O₃-G and P-Fe₂O₃-G

C-Fe₂O₃ and P-Fe₂O₃ with different exposed facets supported on the conductive reduced graphene oxide were

synthesized by a template-free hydrothermal strategy. The reduced graphene oxide (G) interspersed among nanocrystals not only served for a favorable conductive network but also acted as growth matrix to block the aggregation of Fe₂O₃ nanocrystals. The morphology and structure characterizations of C-Fe₂O₃-G and P-Fe₂O₃-G are shown in Figs. 1 and S1–S3. As shown in the scanning electron microscope (SEM) images (Fig. S1), the dispersity of C-Fe₂O₃-G and P-Fe₂O₃-G is almost identical, and C-Fe₂O₃ and P-Fe₂O₃ were both uniformly interspersed on G. The higher-resolution SEM images (Fig. 1a, e) showed that the sizes of C-Fe₂O₃ and P-Fe₂O₃ were similar, and both average edge lengths (the distance between adjacent corners) of two kinds of nanocrystals were estimated to be approximately 300 nm. However, the morphological difference between C-Fe₂O₃ and P-Fe₂O₃ was obvious. The careful observation of the individual Fe₂O₃ nanocrystals at different tilting angles clearly reveals that the shape of C-Fe₂O₃ was concave nanocube (Fig. S2) while the shape of P-Fe₂O₃ was pseudocubic (Fig. S3). The reason that the shape of P-Fe₂O₃ was called as pseudocubic is that its dihedral angles between adjacent flat facets were 94° or 86° (Fig. S3a) [38].

In order to accurately confirm the morphology of C-Fe₂O₃ and P-Fe₂O₃ and analyze their exposed crystal facets, transmission electron microscope (TEM) was employed to characterize their fine structure and surface features. The TEM image of a single C-Fe₂O₃ observed along the [2 $\bar{2}$ 01] direction is shown in Fig. 1b, and the direction of observation was confirmed by the matching select area electron diffraction (SAED) pattern (Fig. 1c), which indicated the single-crystalline nature of C-Fe₂O₃ [38, 47, 48]. A darker contrast in the middle of the nanocrystal than at its margins is obviously viewed in Fig. 1b, verifying the formation of concave structures. This phenomenon was not shown in TEM images of monocrystalline P-Fe₂O₃ observed along same direction (Fig. 1f, g), which was consistent with the formation of pseudocubic enclosed by six equivalent {01 $\bar{1}$ 2} facets (Fig. S4a). In particular, the top view of C-Fe₂O₃ projected along the [2 $\bar{2}$ 01] direction was shown as an approximate concave octagon, which was further proved the formation of the concave surfaces. In comparison with the quadrangular projection drawing of P-Fe₂O₃ (Fig. 1f), the projected concave octagon of C-Fe₂O₃ could perfectly encircle a smaller quadrilateral as marked by the white dotted line in

Fig. 1 **a** SEM image, **b** TEM image, **c** corresponding SAED pattern and **d** HRTEM image of C-Fe₂O₃-G. **e** SEM image, **f** TEM image, **g** corresponding SAED pattern and **h** HRTEM image of P-Fe₂O₃-G. **i** XRD patterns and **j** Fe 2p XPS spectrums of C-Fe₂O₃-G and P-Fe₂O₃-G. The insets in **a** and **e** are the schematic models of C-Fe₂O₃ and P-Fe₂O₃, respectively

Fig. 1b. In addition, as shown in the high-resolution TEM (HRTEM) image acquired from a concave edge of C-Fe₂O₃ (Fig. 1d), the interplanar spacings of crossed lattice fringes with an intersection angle of 94° were all 0.37 nm, which corresponded well to the two adjacent (01 $\bar{1}$ 2) and ($\bar{1}$ 012) facets exposed on an individual P-Fe₂O₃ (Fig. 1h) [49–51]. Based on the above analysis, the concave nanocube could be evolved from the pseudocubic [50], and then, the

exposed crystal planes of C-Fe₂O₃ were indexed as {13 $\bar{4}$ 4} and {12 $\bar{3}$ 8} facets by a series of analyses with the help of geometric models and theoretical formulas (Fig. S4b).

The X-ray powder diffraction (XRD) analysis of C-Fe₂O₃-G and P-Fe₂O₃-G clearly showed that all of the diffraction peaks could be indexed to α -Fe₂O₃ (JCPDS no. 33-0664), which indicated that both of them not only had a high purity but also belonged to the same space group (Fig. 1i). Due

to the reduction of GO to G, the characteristic diffraction peak at 10.4° of GO was not detected in C-Fe₂O₃-G and P-Fe₂O₃-G (Fig. S5) [52, 53]. These component identification results were in agreement with the Raman spectra analysis (Fig. S6). The mass ratios of G to oxide in C-Fe₂O₃-G and P-Fe₂O₃-G were investigated by thermogravimetric analysis (TGA), and the TG curves of them are shown in Fig. S7. The slight weight loss in the initial phase was due to the elimination of the absorbed water on these nanocomposites. Then the significant weight loss appeared on two TG curves, indicating oxidative decomposition of G [53]. Apparently, the mass ratios of G in C-Fe₂O₃-G and P-Fe₂O₃-G were equivalent and the G contents in two composites were both approximately 10.9 wt %, which was consistent with the theoretical calculation value. The Brunauer–Emmett–Teller (BET) specific surface areas of C-Fe₂O₃-G and P-Fe₂O₃-G were calculated using N₂ adsorption–desorption isotherms, which were 19.71 m² g⁻¹ and 20.16 m² g⁻¹ (Fig. S8). Based on the above analysis and exclude unimportant factors, the crystal facet effect on sulfur species between C-Fe₂O₃-G and P-Fe₂O₃-G could be researched systematically.

In general, the adsorption properties and catalytic activity of materials are closely related to their surface environment (chemical composition, element valence and structural characteristics) [33, 37, 40, 49, 54, 55]. X-ray photoelectron spectroscopy (XPS) survey spectrums of C-Fe₂O₃-G and P-Fe₂O₃-G confirmed similar elemental compositions, while the states of some constituent elements are different. The high-resolution Fe 2p spectrums of C-Fe₂O₃-G and P-Fe₂O₃-G both displayed two major peaks at 711 and 724.4 eV (Fig. 1j), ascribed to the typical Fe 2p_{3/2} and Fe 2p_{1/2} orbitals, respectively [49, 52]. Each major peak could be decomposed into two fitted Gaussian components, corresponding to Fe³⁺ and Fe²⁺ species, respectively [56, 57]. The Fe²⁺ / Fe³⁺ ratio of C-Fe₂O₃-G was estimated to be higher than P-Fe₂O₃-G based on the integrated areas of the Fe²⁺ 2p_{3/2} and Fe³⁺ 2p_{3/2} peaks. It indicated that there are more unsaturated coordinated Fe sites existed on the surface of C-Fe₂O₃ with abundant step atoms (the surface atom arrangements of different crystal planes are shown in Figs. 1d, h and S9) [58]. Corresponding to the theoretical simulation (Fig. S10), the coordination analysis of Fe atoms on different crystallographic planes revealed that Fe₂O₃ (1344) and (1238) facets possessed more unsaturated coordinated Fe atoms with dangling bonds in comparison with Fe₂O₃ (0112) facet.

3.2 Comparison of LiPS Adsorption

It is well known that the chemical adsorption of LiPSs is the precondition for their further conversion reactions on the electrocatalyst [33]. Benefiting from the unstable high-index facets with abundant unsaturated coordinated Fe sites, C-Fe₂O₃-G should have a stronger adsorption capacity for LiPSs than P-Fe₂O₃-G. DFT calculations were executed to appraise the ability to anchor LiPSs of C-Fe₂O₃-G and P-Fe₂O₃-G (Fig. 2a–c). The binding energies (E_b) between different exposed crystal facets of two kinds Fe₂O₃ and Li₂S₄ were remarkably different, calculated via a formula ($E_b = E_{\text{Li}_2\text{S}_4+\text{crystal facet}} - E_{\text{crystal facet}} - E_{\text{Li}_2\text{S}_4}$) [59]. The binding energy values of Li₂S₄ on the (1344) and (1238) facets of C-Fe₂O₃ were -1.50 and -1.18 eV, which were more negative than on the (0112) facets of P-Fe₂O₃ (-0.82 eV). Therefore, C-Fe₂O₃-G could anchor Li₂S₄ more efficiently than P-Fe₂O₃-G, owing to the more negative binding energy value signifies a stronger immobilizing effect toward Li₂S₄ [9, 28, 29].

To further validate the stronger interaction between C-Fe₂O₃-G and LiPSs, the visualized adsorption experiments were performed by adding C-Fe₂O₃-G or P-Fe₂O₃-G or G with the same mass into the Li₂S₄ solution. As shown in Fig. 2d, the Li₂S₄ solution with C-Fe₂O₃-G was almost completely faded after static adsorption for 5 h, whereas the Li₂S₄ solutions containing P-Fe₂O₃-G or G still remained gradually deepened yellow. The UV/Vis spectrums of these solutions after aging exhibited that more Li₂S₄ were adsorbed by C-Fe₂O₃-G than others, indicating a superior binding capability toward LiPSs of C-Fe₂O₃-G than P-Fe₂O₃-G and G (Fig. 2e). The visualized adsorption experiments of Li₂S₆ displayed the same results (Fig. S11), which further visually demonstrated the superiority of C-Fe₂O₃-G in adsorbing LiPSs. In addition, XPS analyses of C-Fe₂O₃-G and P-Fe₂O₃-G dried after Li₂S₄ adsorption (C-Fe₂O₃-G-Li₂S₄ and P-Fe₂O₃-G-Li₂S₄) were performed to further reveal the chemical interaction toward Li₂S₄ between C-Fe₂O₃-G and P-Fe₂O₃-G (Fig. 2f). In comparison with pristine nanocomposites without Li₂S₄, the four characteristic peaks of Fe²⁺ 2p_{3/2}, Fe²⁺ 2p_{1/2}, Fe³⁺ 2p_{3/2} and Fe³⁺ 2p_{1/2} overall shifted toward lower binding energies (Fig. 2f), implying the strong chemical interaction between Li₂S₄ and two nanocomposites [60]. Since the four characteristic peaks of C-Fe₂O₃-G located at the same position as those corresponding characteristic peaks of P-Fe₂O₃-G as shown in

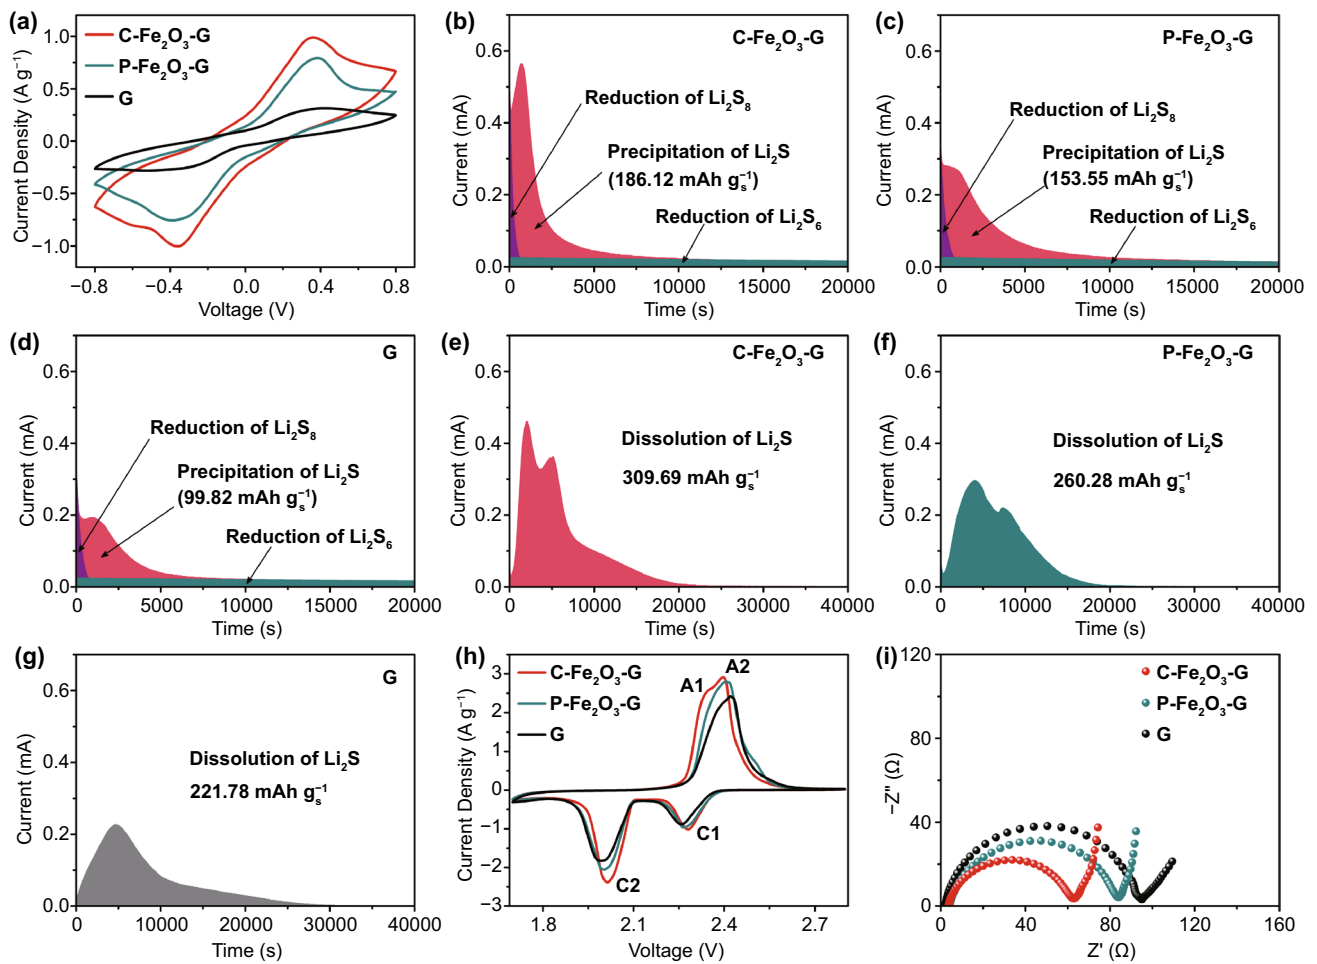

Fig. 3 a CV curves of the symmetric batteries with C-Fe₂O₃-G, P-Fe₂O₃-G and G electrodes. Potentiostatic discharge profiles of Li₂S nucleation on b C-Fe₂O₃-G, c P-Fe₂O₃-G and d G. Potentiostatic charge profile of Li₂S dissolution on e C-Fe₂O₃-G, f P-Fe₂O₃-G and g G. h CV curves and i corresponding Nyquist plots of asymmetrical batteries with C-Fe₂O₃-G, P-Fe₂O₃-G and G

(PP) membrane between two same sulfur-free electrodes and filled with Li₂S₆ electrolyte. Obviously, the CV curve of Li₂S₆ symmetric battery with C-Fe₂O₃-G electrodes displayed a higher polarization current than those with P-Fe₂O₃-G and G electrodes under a scan rate of 5 mV s⁻¹, implying that C-Fe₂O₃-G had significantly stronger effectiveness in enhancing the redox kinetics between liquid-phase LiPSs [59].

In comparison with the liquid–liquid conversion of LiPSs, the liquid–solid–liquid conversion involving the nucleation and decomposition of Li₂S could control the sulfur utilization and specific capacity of Li–S batteries more effectively [61]. Therefore, it was important to evaluate the catalytic effect for the deposition and dissolution of Li₂S by catalyst material [61]. To investigate the Li₂S precipitation process,

simple potentiostatic discharge experiments of C-Fe₂O₃-G, P-Fe₂O₃-G and G electrodes were executed (Fig. 3b–d). The C-Fe₂O₃-G electrode took less time to reach a higher current peak of 0.57 mA than P-Fe₂O₃-G electrode and G electrode under 2.05 V. Meanwhile, the capacity of Li₂S precipitation on C-Fe₂O₃-G (186.12 mAh g⁻¹) was higher than those on P-Fe₂O₃-G (153.55 mAh g⁻¹) and G (99.82 mAh g⁻¹). The above results demonstrated that C-Fe₂O₃-G could markedly facilitate Li₂S nucleation and deposition amounts. In addition, the similar kinetic studies were performed via a potentiostatic decompositions after the galvanostatic discharge processes to verify the superiority of C-Fe₂O₃-G for boosting the dissolution of deposited Li₂S. As shown in Fig. 3e–g, both the oxidation current density and Li₂S dissolution capacity of C-Fe₂O₃-G electrode were higher

compared to those of P-Fe₂O₃-G and G electrodes, revealing that C-Fe₂O₃-G could reduce the oxidation overpotential and enhance the kinetics of Li₂S dissolution and conversion more effectively than the other two materials during charging [33, 59, 61].

3.4 Comparison of Electrochemical Performance

To evaluate the practical superiority of C-Fe₂O₃-G for enhancing the electrochemical kinetics of LiPS transformation in a working Li-S battery, C-Fe₂O₃-G, P-Fe₂O₃-G and G with the same mass were coated on the commercial PP membranes to obtain the functionalized separators. In Fig. S14, C-Fe₂O₃-G and P-Fe₂O₃-G adhered evenly on the PP membrane surface to assemble the faultless interlayers with a thickness of 15 μm. And then, the accelerated redox reactions of sulfur species transformation were explored by CV measurements of Li-S batteries assembled with these functionalized separators between C-S cathodes (Fig. S15) and Li metal anodes at 0.1 mV s⁻¹. The CV curves recorded within a voltage window of 1.7–2.8 V all obviously exhibited the cathodic (reduction) peaks and anodic (oxidation) peaks, which respectively corresponded to the reduction of sulfur to soluble LiPSs [29], LiPSs to Li₂S₂/Li₂S and the oxidation of Li₂S₂/Li₂S to sulfur (Fig. 3h). Obviously, the positive shift of two cathodic peaks to a higher voltage and the negative shift of the anodic peak to a lower voltage, as well as the enhanced current of all redox peaks were exhibited on the cell with C-Fe₂O₃-G interlayer (C-Fe₂O₃-G cell) compared to those with P-Fe₂O₃-G and G interlayers (P-Fe₂O₃-G cell and G cell), indicating that C-Fe₂O₃-G had more robust catalytic ability to enhance the redox kinetics of LiPSs [9–11, 33, 59]. The peculiar A1 peak appeared only on the CV curve of C-Fe₂O₃-G cell, which signified a rapid Li₂S dissolution behavior on C-Fe₂O₃-G than others [29]. Furthermore, in comparison with P-Fe₂O₃-G cell and G cell, the electrochemical impedance spectroscopy (EIS) of C-Fe₂O₃-G cell showed the smallest charge transfer resistance, manifesting the superior interfacial charge conductivity under C-Fe₂O₃-G electrocatalysis, which resulted in the accelerated sulfur redox kinetics (Fig. 3i).

Subsequently, CV measurements were also implemented under higher scan rates (0.2 to 0.6 mV s⁻¹) to investigate lithium-ion diffusion coefficients, which were another important impact factor for the transformation kinetics of

LiPSs [61], to confirm the superior electrochemical performance of C-Fe₂O₃-G in LiPS conversion. All reduction and oxidation peak currents varied linearly with the square root of scanning rate, and the slopes of the curves obtained from the linear fitting of peak currents were positively interrelated with the corresponding lithium-ion diffusion in cells with different interlayers (Fig. S16). Evidently, C-Fe₂O₃-G cell exhibited the largest slope value in each reduction and oxidation reaction of sulfur species, which certified the superiority of C-Fe₂O₃-G in accelerating mass transfer and LiPS redox kinetics during discharge/charge [29, 61]. To further demonstrate the faster lithium-ion transport kinetics of the C-Fe₂O₃-G, the galvanostatic intermittent titration technique (GITT) was employed to analyze the lithium-ion diffusion coefficient (D_{Li^+}) in three battery systems (Fig. S17a-c). The calculated D_{Li^+} values in C-Fe₂O₃-G cell were larger than those in P-Fe₂O₃-G and G cells (Fig. S17d), further confirming the superiority of C-Fe₂O₃-G in accelerating the lithium-ion transfer.

The galvanostatic charge–discharge measurements of the cells with different catalytic materials under 0.1 C also revealed similar results matched with the above analyses. The charge–discharge curves within a cutoff voltage of 1.7–2.8 V showed two discharge plateaus and a charge plateau, respectively, assigning to the reduction and oxidation peaks of CV curves (Fig. 4a). In comparison with P-Fe₂O₃-G cell and G cell, C-Fe₂O₃-G cell manifested higher discharge capacity at the first voltage plateau (Q_1) and second voltage plateau (Q_2) as well as larger capacity ratio of Q_2 to Q_1 , which not only indicated the superiority in suppressing the shuttling of LiPSs but also verified the stronger catalytic effect in promoting the conversion of LiPSs to unsolvable Li₂S [59]. The cell with C-Fe₂O₃-G exhibited the smallest polarization ($\Delta E_1 = 0.1522$ V) than those with P-Fe₂O₃-G ($\Delta E_2 = 0.1848$ V) and G ($\Delta E_3 = 0.2036$ V), further proving the enhanced electrochemical kinetics stemming from C-Fe₂O₃-G. In the charge process, the smallest initial charge potential barrier was displayed on the curve of C-Fe₂O₃-G cell, which implied a most robust catalytic effect of C-Fe₂O₃-G in the decomposition of Li₂S (Fig. 4b) [33, 59].

To further validate the significant impact of C-Fe₂O₃-G on boosting the sulfur redox kinetics, the rate capacities of the batteries assembled with different interlayers were first evaluated under increasing current density from 0.1 to 4.0 C (Fig. 4c). C-Fe₂O₃-G cell exhibited the highest initial discharge capacity of 1521 mAh g⁻¹ at 0.1 C among three

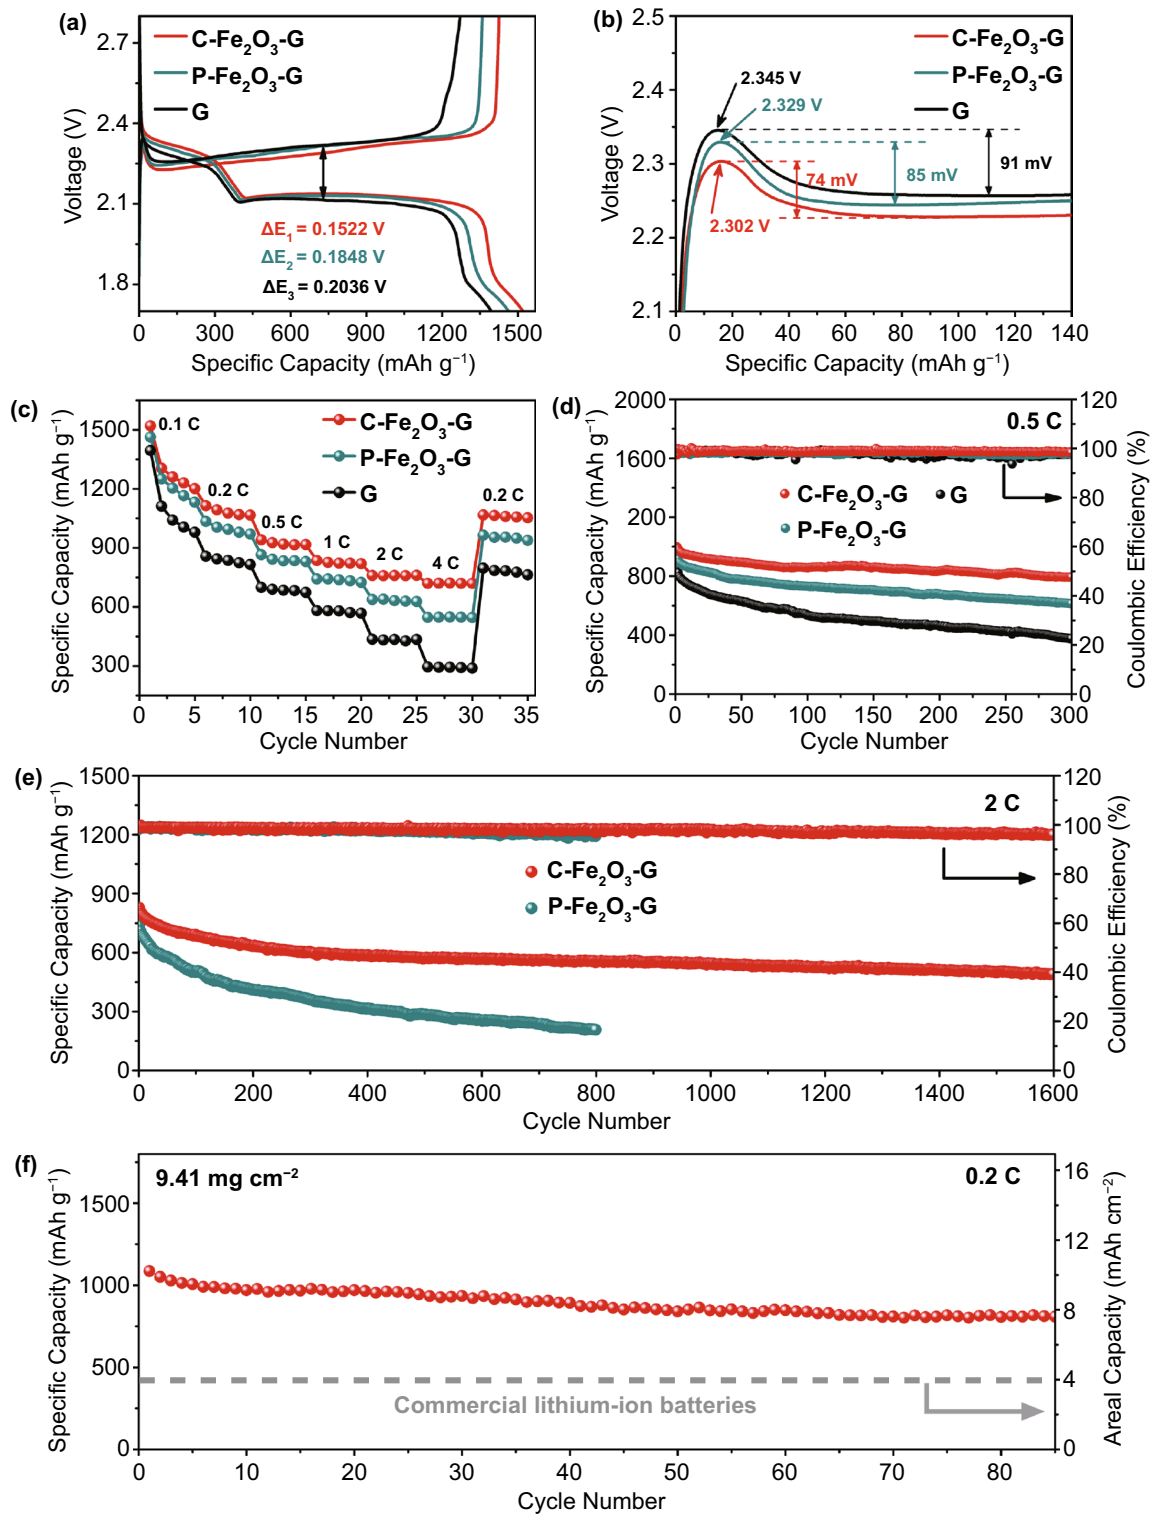

Fig. 4 **a** Galvanostatic charge/discharge profiles and **b** charge voltage profiles of C- Fe_2O_3 -G, P- Fe_2O_3 -G and G cells at 0.1C. **c** Rate capacities and **d** cycle performance at 0.5 C of C- Fe_2O_3 -G, P- Fe_2O_3 -G and G cells. **e** Long-term cycle stability of C- Fe_2O_3 -G and P- Fe_2O_3 -G cells at 2 C. **f** Cycling performance of C- Fe_2O_3 -G cell with high sulfur loading of 9.41 mg cm^{-2} at 0.2 C

battery systems with the sulfur loading of 1.0–1.4 mg cm⁻². When increasing the electric current density to 0.2, 0.5, 1.0, 2.0 and 4.0 C, the reversible discharge capacities of C-Fe₂O₃-G cell could still reach 1115, 941, 835, 760 and 719 mAh g⁻¹, respectively, which were much higher than the corresponding capacities of P-Fe₂O₃-G cell and G cell. Moreover, the capacity gaps between C-Fe₂O₃-G cell and the other two cells with P-Fe₂O₃-G or G gradually expanded with the increase of electric current density, respectively, attaining 172 and 424 mAh g⁻¹ at 4.0 C. The corresponding charge–discharge profiles of three batteries at different current densities were recorded, as shown in Fig. S18. Even at a high current densities of 4.0 C, C-Fe₂O₃-G cell still maintained two well-defined discharge plateaus, exhibiting the higher electrochemical stability than two other cell systems. These test results all demonstrated that C-Fe₂O₃-G could not only more evidently alleviate the shuttling of LiPSs but also enhance the utilization of sulfur more effectively, which possibly profited from the excellent adsorption capacity and catalytic activity of the high-index crystal facets exposed on C-Fe₂O₃-G.

The enhanced cycling stability of Li–S batteries with C-Fe₂O₃-G catalysts was also testified via an endurance test under the galvanostatic mode. The cycle performances at 0.5 C of the batteries with C-Fe₂O₃-G, P-Fe₂O₃-G and G are shown in Fig. 4d. It was clear that C-Fe₂O₃-G cell delivered higher initial discharge capacities in comparison with P-Fe₂O₃-G cell and G cell, revealing that C-Fe₂O₃-G interlayer could reduce the loss of the active sulfur components most effectively [29, 59]. After continuous 300 cycles, C-Fe₂O₃-G cell held a high reversible capacity of 788 mAh g⁻¹ with high average Coulombic efficiency (> 98.5%), corresponding to the average capacity fading of 0.069% each cycle. By contrast, P-Fe₂O₃-G cell and G cell, respectively, retained discharge capacities of 616 and 349 mAh g⁻¹ after 300 cycles at 0.5 C, respectively, corresponding to two higher capacity decay rates. Consequently, the battery with C-Fe₂O₃-G catalyst showed better cycling stability under a low current rate of 0.5 C. The long-term cycling stability measurements were also taken under a higher current rate of 2.0 C, and the corresponding results are shown in Fig. 4e. C-Fe₂O₃-G cell exhibited a higher premier discharge capacity and much better cycling performance than P-Fe₂O₃-G cell. After 1600 continuous discharging–charging cycle tests, C-Fe₂O₃-G cell still maintained a reversible discharge capacity of 491 mAh g⁻¹, achieving a capacity fading rate

as low as 0.025% every cycle. Besides, the good voltage stability during the long-term charge–discharge cycles further manifested the excellent electrochemical stability of C-Fe₂O₃-G cell (Fig. S19). In comparison, the discharge specific capacity of P-Fe₂O₃-G cell decayed to 209 mAh g⁻¹ after 800 continuous cycles, and the capacity fading of each cycle was 0.089%, revealing the worse long-term cycling stability than C-Fe₂O₃-G cell at 2.0 C. In addition, the Coulombic efficiency of C-Fe₂O₃-G cells had smaller decline compared with P-Fe₂O₃-G cells both at 0.5 and 2.0 C, implying better inhibition of C-Fe₂O₃-G for LiPS shuttling. The effective suppression of LiPS shuttling would guarantee the slightest corrosions of Li anode, which was identified by the characterization of Li metal anodes in Fig. S20. The long-term cycling stability of C-Fe₂O₃-G cell at a higher current density of 4.0 C was also recorded under the galvanostatic mode. As shown in Fig. S21, C-Fe₂O₃-G cell exhibited the good long-term cycling stability at 4.0 C, which further confirmed the superiority of C-Fe₂O₃-G in improving the performance of Li–S batteries.

The chemical stability of C-Fe₂O₃-G during the charge–discharge cycle was certified by XRD and XPS analyses. As shown in Fig. S22, all the XRD diffraction peaks of the cycled C-Fe₂O₃-G highly matched with the new C-Fe₂O₃-G. Moreover, the characteristic peak of Fe–S bond did not appear in the high-resolution Fe 2p spectrums of the cycled C-Fe₂O₃-G (Fig. S23). All these characterization results indicated that the sulfidation reaction of C-Fe₂O₃-G by sulfur species did not occur during cycling, which proved the excellent chemical stability of C-Fe₂O₃-G in lithium–sulfur batteries. Taking into account the high requirement of energy density in practical applications, the cycle performances of C-Fe₂O₃-G cell with a high sulfur loading of 9.41 mg cm⁻² was investigated under the galvanostatic mode. The battery with C-Fe₂O₃-G electrocatalysts, respectively, delivered discharge capacity of 1192 and 1087 mAh g⁻¹ at 0.1 and 0.2 C (Fig. S24). After 85 continuous discharging–charging cycles at 0.2 C, the cell maintained a reversible discharge capacity of 809 mAh g⁻¹, corresponding to a favorable areal capacity of 7.61 mAh cm⁻², which was much superior to the commercial LIBs. This high discharge capacity and superior rate performance as well as outstanding cycle span are prominent in comparison with previous works (Table S1). All the research results confirmed that C-Fe₂O₃-G with high-index crystal faces could effectively elevate the electrochemical performance of sulfur species

in a working battery, which was conducive to the practical application of Li-S batteries.

3.5 DFT Analysis

The DFT calculations were carried out to further uncover the mechanism of C-Fe₂O₃-G electrocatalysts more efficiently inhibiting the shuttling of LiPSs and accelerating the redox kinetics of sulfur species. The projected density of states (PDOS) of Fe-3d orbitals for different crystal facets before and after interacting with Li₂S₄ is shown in Fig. 5a, revealing

the electronic configuration of Fe center, which was related to surface adsorbability and catalytic activity of Fe-based catalysts [59]. In Fig. 5b, the d-band centers of Fe atoms on the (13̄44) (−2.26 eV) and (12̄38) (−2.33 eV) facets of C-Fe₂O₃ were closer toward the Fermi level than those on Fe₂O₃ (01̄12) facet (−2.47 eV), indicating the stronger adsorption capacity and better electronic conductivity on Fe₂O₃ (13̄44) and (12̄38) facets, which would be beneficial to the adsorption and further conversion of LiPSs [9, 59, 62]. After interacting with LiPSs, the d-band center of Fe atoms on Fe₂O₃ (13̄44) facet shifted more obviously to the Fermi level compared to those on the other two crystal

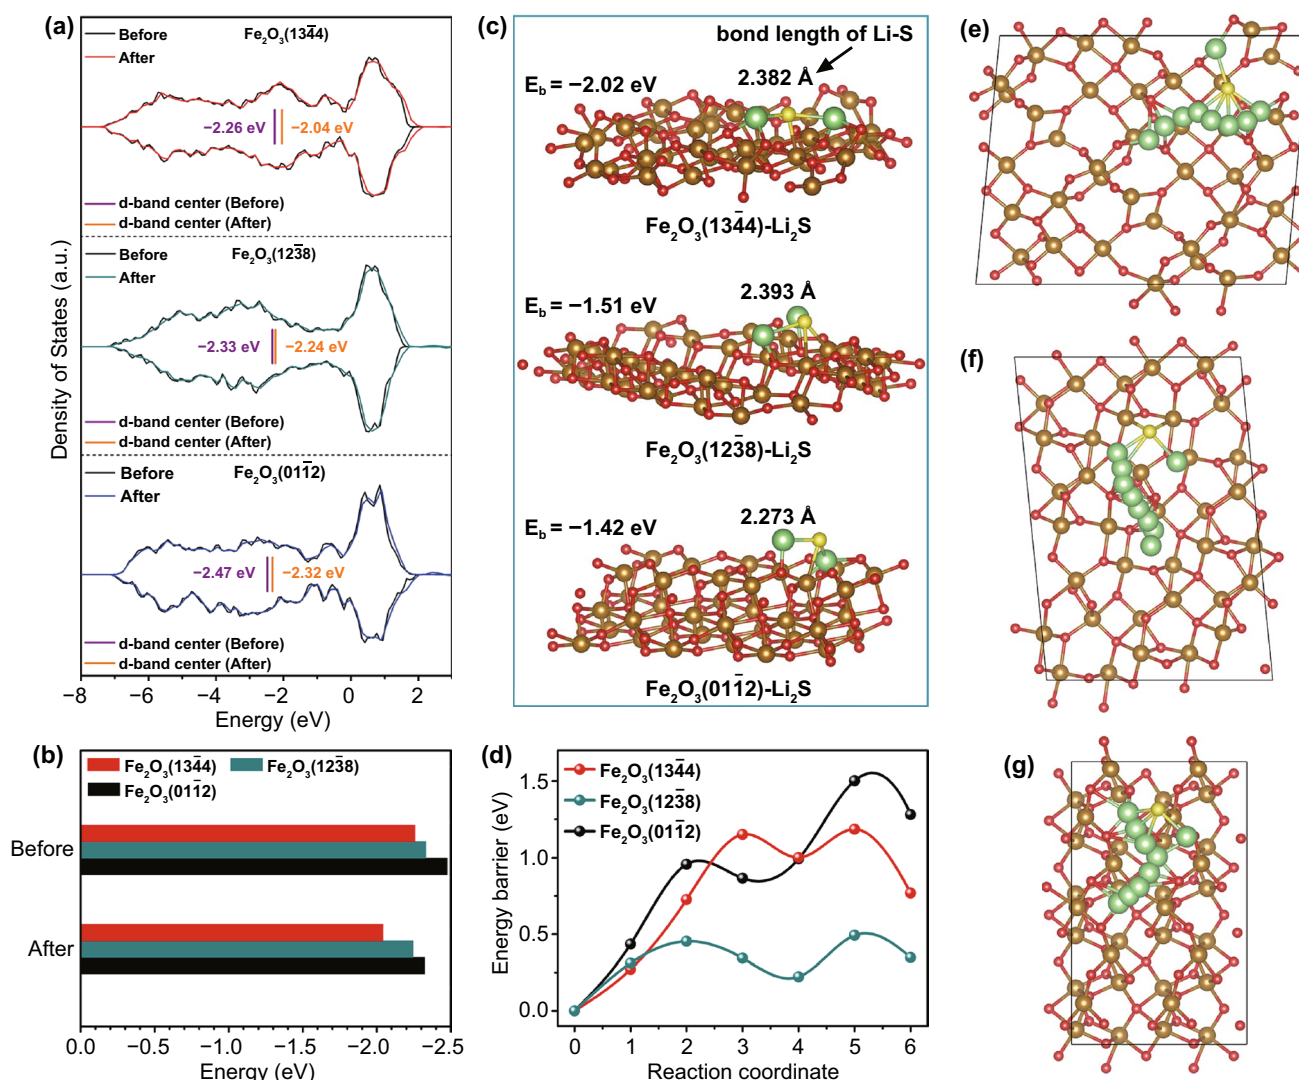

Fig. 5 **a** Projected density of states and **b** d-band center of the Fe atoms exposed on different Fe₂O₃ crystal planes before and after interacting with Li₂S₄. **c** Optimized geometries and **d** decomposition energy barriers of Li₂S adsorbed on different Fe₂O₃ crystal faces. **e–g** Li₂S decomposition path on Fe₂O₃ (1344), (1238) and (0112) facets. The Li, S, Fe and O atoms are severally indicated by green, yellow, gold and red balls

facets, corresponding to the strongest interaction between catalyst surface and adsorbates [63]. Li_2S_4 adsorbed on Fe_2O_3 (1344) facet displayed an unusual distorted geometry with broken Li–S and S–S bond (Fig. 2a), reflecting that Fe_2O_3 (1344) facets could adsorb and activate Li_2S_4 more effectively and expedite the decomposition of Li_2S_4 [29]. In addition, the adsorption of Li_2S on different Fe_2O_3 crystal faces was analyzed by DFT calculations (Figs. 5c and S25). The calculated binding energies of Li_2S on Fe_2O_3 (1344) and (1238) facets were -2.02 and -1.51 eV, respectively, which were more negative in comparison with that on Fe_2O_3 (0112) facet (-1.42 eV), availing more uniform Li_2S nucleation and deposition [59]. It is worth noting that the bond lengths of Li–S in adsorbed Li_2S both on Fe_2O_3 (1344) (2.382 Å) and (1238) (2.393 Å) facets were significantly longer than that on Fe_2O_3 (0112) facet (2.273 Å), which suggested that C- Fe_2O_3 as catalysts could more efficiently weaken the binding between Li and S of Li_2S and then reduce the decomposition energy barrier of Li_2S [64]. Afterward, the superiority of C- Fe_2O_3 was further confirmed by the theoretical analysis of decomposition energy barrier of Li_2S on different Fe_2O_3 crystal faces. The energy profiles of Li_2S decomposition and corresponding decomposition path are shown in Fig. 5d–g. The decomposition energy barriers of Li_2S on Fe_2O_3 (1238) (0.49 eV) and (1344) (1.18 eV) facets were significantly lower than that on Fe_2O_3 (0112) facet (1.51 eV), which revealed that C- Fe_2O_3 possessed stronger catalytic capacity to break Li–S bonds more easily and enhance the oxidative decomposition kinetics of Li_2S [65]. These theoretical calculation results all demonstrated that the higher sulfur utilization and faster reversible conversion of sulfur species could realize with the help of C- Fe_2O_3 -G catalysts compared with P- Fe_2O_3 -G, which was in good agreement with electrochemical measurement results.

4 Conclusions

We successfully constructed Fe_2O_3 concave nanocubes with high-index facets anchored on reduced graphene oxide through a simple hydrothermal strategy and applied it as the electrocatalysts to investigate the structure–activity relationship between the surface structures of crystal

materials and its chemisorption/catalytic conversion for sulfur species. Experiment researches and DFT results all revealed that the strong adsorption capacity and high catalytic activity of C- Fe_2O_3 -G stemmed from the active high-index Fe_2O_3 crystal faces with abundant unsaturated Fe sites. These high-activity crystal facets could not only enhance chemisorption of LiPSs but also accelerate the liquid–solid conversion of LiPSs and the oxidative decomposition of Li_2S , which significantly improve the utilization of sulfur. Therefore, the batteries with C- Fe_2O_3 -G catalysts delivered an outstanding premier discharge capacity of 1521 mAh g^{-1} at 0.1 C, as well as the stable cycling performance during 1600 cycles at 2C with a low capacity decaying of 0.025% every cycle. Moreover, the battery with a high sulfur loading of 9.41 mg cm^{-2} cycled steadily at 0.2 C and a high areal capacity of 7.61 mAh cm^{-2} was maintained after 85 cycles. This work exhibited pioneering insights into the crystal facet effect in Li–S electrochemistry and provided instructive guidance for fabricating novel catalysts applied in advanced Li–S batteries by tuning the surface structure of materials.
